Abstract: Obesity is a growing public health problem, which has now been considered as a pandemic non-communicable disease. However, the efficacy of several approaches for weight loss is limited and variable. Thus, alternative anti-obesity treatments are urgently warranted, which should be effective, safe and widely available. Active compounds isolated from herbs are similar with the practice of Traditional Chinese Medicine, which has a holistic approach that can targets to several organs and tissues in the whole body. Capsaicin, a major active compound from chili peppers, has been clearly demonstrated for its numerous beneficial roles in health. In this review, we will focus on the a less highlighted aspect, in particular how dietary chili peppers and capsaicin consumption reduce body weight and its potential mechanisms of its anti-obesity effects. With the widespread pandemic of overweight and obesity, the development of more strategies for the treatment of obesity is urgent. Therefore, a better understanding of the role and mechanism of dietary capsaicin consumption and metabolic health can provide critical implications for the early prevention and treatment of obesity.

Keywords: Capsaicin; obesity; TRPV1; adipogenesis; brown adipose tissue; appetite

Abbreviations (alphabetically): BAT, brown adipose tissue; BMI, body mass index; BMP8b, bone morphogenetic protein-8b; cAMP, cyclic adenosine monophosphate; C/EBP-α, CCAAT-enhancer-binding protein-α; PKA, protein kinase A; GLP-1, glucagon-like peptide-1; GPDH, glycerol-3-phosphate dehydrogenase; Muc2, mucin 2 gene; NF-κB, nuclear factor- kappa B; PPARα, peroxisome proliferator activated receptor α; PPARγ, peroxisome proliferator activated receptor-γ; PRDM-16, positive regulatory domain containing 16; PGC1-α, PPARγ coactivator 1-α; Reg3g, regenerating islet-derived protein 3 gamma; SIRT-1, sirtuin-1; STAT-3, signal transducer and activator of transcription-3; T2DM: type 2 diabetes mellitus; TRPV1, transient receptor potential vanilloid 1; UCP-1, uncoupling protein 1; WAT, white adipose tissue; WHO: World Health Organization.
1. Introduction

The epidemic of obesity is a growing public health problem. The incidence of obesity has more than doubled since 1980, and has now reached worldwide epidemic status [1]. In 2014, the World Health Organization (WHO) estimated that 39% of the human adult population with 1.9 billion people were affected with overweight (body mass index (BMI) $\geq 25$ kg/m$^2$), and that obesity (BMI $\geq 30$ kg/m$^2$) affected about 13% with 600 million people [2, 3]. Obesity is a serious risk factor as it is associated with chronic inflammation and metabolic syndrome [4], a cluster of morbidities that includes hypertension, hyperlipidemia and type 2 diabetes mellitus (T2DM) [5]. It can increase the risks of developing serious health problems, such as cardiovascular diseases, chronic kidney disease and stroke [6, 7]. Moreover, obese patients are more prone to contract several forms of cancer with reduced chances of survival [8]. Of particular concern is the incidence of overweight and obesity in children, with an estimated one-third of children and adolescents affected in the United States and over 41 million children are overweight before reaching puberty [2]. As such, obesity and its related diseases yield enormous tolls at individual, public health and economic levels. In addition, genome-wide association studies (GWAS) have revealed compelling genetic signals influencing obesity risk and genetic polymorphism plays a major role in determining obesity [9]. An updated randomized controlled trial indicated that greater body weight and waist circumference reductions in risk carriers than in nonrisk carriers of the fat-mass and obesity-associated (FTO) gene across different levels of personalized nutrition [10]. These data signify that the interventions should be personalized and varies with each individual [11]. Thus, the development of novel and personalized strategies for the early prevention and treatment of overweight and obesity is warrant.

2. Limitations in anti-obesity approaches

It has clearly established that weight loss will significantly diminish the complications of
obesity [12]. Emerging human epidemiology studies indicated that reducing body weight, with weight loss of at least 5%, has long-term benefits on metabolic health and reduces the risks of developing insulin resistance, T2DM and cardiovascular diseases [13]. However, weight loss is difficult and the obese individuals are struggling to achieve it and the efficacy of several approaches for weight loss is limited and variable [14, 15]. Firstly, it is widely accepted that a combination of physical exercise and low calorie diet is the best approach to prevent and treat obesity. However, this strategy is difficult to implement and its compliance is poor. Gupta et al. aimed to explored treatment satisfaction associated with different weight loss methods among patients with obesity. It showed that using self-modification weight loss techniques, such as, diet, exercise and weight loss supplements has lowest treatment satisfaction, compared with gastric bypass and gastric banding, and prescription medication [16]. In addition, physical exercise and diet intervention also yield enormous tolls at economic level. It reported that retail sales of weight-loss supplements were estimated to be more than $1.3 billion in 2001 in US [17]. Thus, cheap, easily available therapies and supplements are urgently needed. The second approach is pharmaceutical drugs, such as Orlistat, a potent and specific inhibitor of intestinal lipases. It can reduce body weight with an average weight loss of 3% during one year period [13]. However, its efficacy is variable and it can lead to gastrointestinal adverse effects, liver failure and acute kidney injury [18]. Other anti-obesity drugs, such as rimonabant, fenfluramine and sibutramine, have been withdrawn from the market due to severe adverse effects, including increased cardiovascular risks, mood disorders and even suicidal susceptibility [14]. Thirdly, anti-diabetic agents, such as, glucagon-like peptide 1 (GLP-1) analogue, liraglutide has been shown its potential anti-obesity efficacy [19]. But it needs to be injected subcutaneously daily. Moreover, the weight loss is limited and it can increase the risk of pancreatitis [20]. Compared with aforementioned anti-obesity drugs, bariatric surgery such as Roux-en-Y gastric bypass or sleeve gastrectomy is more effective. However, it is physically invasive, relatively expensive
and its long-term effect is unclear [21]. Therefore, alternative anti-obesity treatments are urgently warranted, which should be effective, safe and widely available.

3. An overview of chili peppers and capsaicin

Chili pepper is generally used as a flavoring spice and is prominent in diets of various communities and cultures worldwide since 7000BC, with a long history of flavoring, coloring, preserving food as well as medication [26]. In chili pepper, more than 200 active constituents have been identified and some of its active constituents play multiple roles in the whole body [27]. Capsaicin, as a major active compound from chili pepper, has been established for its numerous beneficial roles in the human organism, including the treatment of pain inflammation, rheumatoid arthritis [28] and vasomotor rhinitis [29] (Figure 1). Furthermore, capsaicin has proven an effective anti-cancer agent. Several preclinical studies showed that capsaicin could suppress various human neoplasia by generating reactive oxygen species and increasing apoptosis [30, 31]. Finally, capsaicin demonstrated significant antioxidant properties and it was postulated that this compound has important implications in the prevention or treatment of neurodegenerative diseases such as Alzheimer’s disease [32]. In addition to capsaicin as anti-obesity compounds, other types of natural products also have shown to be considered as anti-obesity compounds. Celastrol (from roots of the thunder god vine) can reduce appetite and food intake in mice that are fed a high-fat diet [33]. Stilbenoid resveratrol (from grapes and red wine), genistein (an isoflavone from soy), glycyrrhizin (from liquorice), quercetin, ethanolic extract (from ginseng roots) and green tea extract (including camellia sinensis, catechin, caffeine, and epigallocatechin gallate), play a role in adipogenesis inhibition, thus may have anti-obesity potency [15]. In this review, we will focuses on the a less highlighted aspect, in particular how dietary chili peppers and capsaicin consumption reduce body weight and its potential mechanisms of its anti-obesity effects. Figure 1 shows the molecular structure of capsaicin and isolated from chili peppers.
4. Clinical studies of the weight-loss effects of capsaicin

4.1 Weight-loss effects of capsaicin on lipid oxidation and energy expenditure

Epidemiological data revealed that the consumption of foods containing capsaicin was associated with a lower prevalence of obesity [34]. In one double-blind, randomized, placebo controlled trial, it indicated that treatment of overweight or obese subjects with 6 mg/d capsinoid for 12 weeks was associated with abdominal fat loss measured by dual energy X-ray absorptiometry. Body weight was decreased as 0.9 and 0.5 kg in the capsinoid and placebo groups, respectively. Moreover, none of the patients developed any adverse events [35] (Table 1). Lejeune et al. aimed to investigate whether capsaicin assists weight maintenance by limiting weight regain after weight loss of 5% to 10%. The results showed that capsaicin treatment caused sustained fat oxidation during weight maintenance compared with placebo [36] (Table 1). Increase the oxygen consumption (VO$_2$) and body temperature, reflecting increased energy expenditure, thus play critical role in weight loss. Fat oxidation was reported to be sustained together with elevation of the resting energy expenditure and enhanced fat oxidation may contribute to increased energy expenditure. In another randomized double-blind study, it indicated that subjects between 30 and 65-year old with a BMI >23 kg/m$^2$ treated with capsinoid (10 mg/kg per day) for 4 weeks safely and body weight tended to decrease during the 2 to 4 week period, with increased VO$_2$, resting energy expenditure, fat oxidation significantly [37] (Table 1). Enhanced lipid oxidation and increased energy expenditure are potentially beneficial for weight management [38].

4.2 Weight-loss effects of capsaicin on appetite and brown adipose tissue

Dietary red pepper can suppress energy intake and modify macronutrient intake through appetite and satiety regulation [39]. One prospective study aimed to investigate the effects of capsaicin on feeding behavior and energy intake. It indicated that the addition of red pepper to the breakfast significantly decreased protein and fat intakes at lunch time.
and the addition of red pepper to the appetizer significantly reduced the cumulative ad libitum energy and carbohydrate intakes during the rest of the lunch. These effects might be related to an increase in sympathetic nervous system activity [40] (Table 1). Brown adipose tissue (BAT) is known to play a critical role in cold-induced non-shivering thermogenesis to maintain body temperature and it is expected to be a therapeutic target for obesity and related metabolic disorders in humans [41]. It showed Chili pepper affects energy expenditure by triggering the BAT in the same way as low temperature does, leading to increased energy expenditure via non-shivering thermogenesis [42]. One recent clinical study showed that 9 mg of capsinoid for 8 weeks could increase BAT activity and increase thermogenesis in healthy subjects [43] (Table 1). The results suggest dietary capsaicin consumption could have a beneficial effect for weight management, by reducing energy intake and activation of brown adipose tissue activity. The summary of the clinical studies about the weight-loss effects of capsaicin was shown Table 1.

5. Pre-clinical studies about anti-obesity effects of capsaicin and its potential mechanisms

5.1 Capsaicin and TRPV1 activation

Numerous epidemiology studies and animal studies indicated that capsaicin, as a transient receptor potential vanilloid 1 (TRPV1) agonist, it may represent a potential strategy to treat obesity. Although it is well accepted much of the effect is caused by stimulation of the TRPV1 receptor, the mechanism of action is not presently fully understood. Increasing evidence indicates that TRPV1 plays a critical role in the regulation of metabolic health for the whole body, including body weight, glucose and lipid metabolism, and cardiovascular system [44, 45]. TRPV1 was deemed as a potential target for the prevention of obesity due to its effect on energy metabolism and balance [46, 47]. Activation of TRPV1 by capsaicin can attenuate abnormal glucose homeostasis by stimulating insulin secretion and increasing glucagon-like peptide-1 (GLP-1) levels [48,
Furthermore, capsaicin also plays its role in a receptor-independent manner. It reported that capsaicin was associated with nuclear factor- kappa B (NF-κB) inactivation and peroxisome proliferator activated receptor-γ (PPARγ) activation, and then it could modulate adipocyte function of adipose tissues in obese-mouse and suppressed the inflammatory responses of adipose tissue macrophages, which is independent on TRPV1 [50]. Additionally, TRPV1 can play a critical role in cell proliferation and cancer. It showed that TRPV1 implicated as a regulator of growth factor signaling in the intestinal epithelium, which could subsequent suppress intestinal tumorigenesis [51].

The potential mechanisms underlying the anti-obesity effects of capsaicin include: (1) increase lipid oxidation and inhibit adipogenesis; (2) activate brown adipose tissue (BAT) activity and induce thermogenesis; (3) suppress appetite and increase satiety regulated by neuronal circuits in the hypothalamus; (4) modulate the function of gastrointestinal tract and gut microbiome. The molecular mechanisms of the anti-obesity effects of capsaicin were summarized in Figure 2. In addition, we further collected most pre-clinical studies, including in-vitro studies and rodent experiments about the anti-obesity effects of capsaicin (shown in Table 2).

5.2 Capsaicin and its role in adipogenesis

Adipogenesis is the critical and original process of fatty adipose accumulation. It suggested that decreased preadipocyte differentiation, proliferation and lipogenesis have the potential to reduce obesity. Hsu et al. demonstrated that capsaicin inhibited the expression of PPARγ, CCAAT-enhancer-binding protein-α (C/EBP-α) and leptin, but induced up-regulation of adiponectin at the protein level. Thus, it efficiently induced apoptosis and inhibits adipogenesis in 3T3-L1 preadipocytes and adipocytes in vitro [52] (Table 2, Figure 2). Zhang et al. found that capsaicin treatment prevented adipogenesis of 3T3-L1-preadipocytes in vitro, with increased intracellular calcium [53] (Figure 2). Male
C57BL/6 obese mice fed a high-fat diet for 10 weeks received a supplement of 0.015% capsaicin showed decreased fasting glucose, insulin, leptin concentrations, and markedly improved glucose intolerance in obese mice, accompanied with decreased TRPV-1 expression in adipose tissue, increased adiponectin expression in the adipose tissue and increased peroxisome proliferator activated receptor α (PPARα) and PPARγ coactivator 1-α (PGC-1α) expression in the liver [54] (Table 2, Figure 2). Ohnuki et al. demonstrated that mice treated with 10 mg/kg body weight capsaicin could markedly suppressed body fat accumulation and promoted energy metabolism [55] (Table 2). Hence, these studies supported that capsaicin could decrease adipogenesis and regulate genes function related with lipid metabolism, and then it can has the potential to lose weight.

5.3 Capsaicin and its role in brown adipose tissue

BAT is the main site of adaptive thermogenesis and experimental studies have associated BAT activity with protection against obesity and metabolic diseases [56]. A review illustrated that the activity of BAT can be activated and recruited not only by cold exposure but also by various food ingredients, such as capsaicin in chili pepper [57] (Table 2). Capsinoids supplementation with exercise in C57BL/6J mice additively decreased body weight gain and fat accumulation, and increased whole body energy expenditure compared with exercise alone. The underlying mechanisms may be associated with increased energy expenditure, lipolysis activation in BAT and increased cyclic adenosine monophosphate (cAMP) levels and protein kinase A (PKA) activity in BAT [58] (Table 2, Figure 2). One up-to-date rodent experiment showed that capsaicin could counter the detrimental effects of high-fat diet, including glucose intolerance, hypercholesterolemia and suppressed activity in BAT. These effects were mainly by increasing the expression of metabolically important thermogenic genes, including uncoupling protein 1 (UCP-1), bone morphogenetic protein-8b (BMP8b), sirtuin-1 (SIRT-1), PGC-1α and PR domain containing zinc finger protein 16 (PRDM-16) in BAT. Furthermore, capsaicin supplementation, post high-fat diet, promoted weight loss and
enhanced the respiratory exchange ratio. All these data suggested that capsaicin is a novel strategy to counter diet-induced obesity by enhancing metabolism and energy expenditure [59] (Table 2, Figure 2). Baskaran et al. showed that activation of TRPV1 channels by dietary capsaicin triggered browning of adipose tissue to counteract obesity [60] (Table 2). Collectively, these observations provide evidence that capsaicin can activate and recruit BAT, which would be a promising strategy to counter obesity.

5.4 Capsaicin and its role in appetite and satiety

Energy balance requires an ability of the brain to detect the status of energy stores and match energy intake with expenditure, and energy homeostasis is mainly controlled by neuronal circuits in the hypothalamus [61]. Hypothalamic endoplasmic reticulum stress occurs in individuals with obesity and is thought to induce low levels of leptin receptor signaling and play a central role in development of leptin resistance [62]. The adipose tissue-derived hormone leptin acts via its receptor in the brain to regulate energy balance and neuroendocrine function. Leptin resistance is a pathological condition, which means the lack of appetite reduction in response to leptin and the body fails to adequately respond to it [63]. Lee et al. found that TRPV1 had a major role in regulating glucose metabolism and hypothalamic leptin's effects in obesity, with hypothalamic signal transducer and activator of transcription-3 (STAT-3) activity blunted in the TRPV1 knock out mice [64] (Figure 2). Addition of dietary capsaicin has been shown to increase satiety and it indicated that capsaicin increased sensation of fullness in energy balance, and decreased desire to eat after dinner in negative energy balance [65]. Although the studies about capsaicin and its role in appetite is limited, it inspired us that neuronal circuits in the hypothalamus may be a pivotal target of capsaicin.

5.5 Capsaicin and its role in gastrointestinal tract and gut microbiome

Capsaicin is passively absorbed in the stomach with greater than 80% efficiency and upper portion of the small intestine [66]. Thus, it may activate local TRPV1 channels in
gastrointestinal tract to initiate a series of physiological effects. Dietary capsaicin consumption triggered the intestinal mucosal afferent nerves and increased intestinal blood flow [67]. Acute single administration of 640 umol/L capsaicin into the duodenal lumen in anesthetized rats significantly increases superior mesenteric artery blood flow [68] (Table 2). In addition, it showed that dietary capsaicin ameliorated abnormal glucose homeostasis and increased GLP-1 levels in the plasma and ileum through the activation of TRPV1-mediated GLP-1 secretion in the intestinal cells and tissues [49] (Table 2, Figure 2). Recent study demonstrated that anti-obesity effect of capsaicin in mice fed with high-fat diet was associated with an increase in population of the gut bacterium Akkermansia muciniphila. Further studies found that capsaicin directly up-regulated the expression of Mucin 2 gene Muc2 and antimicrobial protein gene regenerating islet-derived protein 3 gamma (Reg3g) in the intestine[69] (Table 2, Figure 2). These data suggested that the anti-obesity effect of capsaicin is associated with a modest modulation of the function in gastrointestinal tract and gut microbiome.

6. Conclusion

In summary, capsaicin plays a critical role in human and has multiple benefits for metabolic health, especially for weight loss in obese individuals. It is well accepted that the potential application of active compounds isolated from herbs are similar with the practice of traditional Chinese medicine, which has a holistic approach that can targets to different organs and tissues in the whole body. More importantly, no adverse effects with capsaicin were observed in most studies. Thus, chili peppers and capsaicin are safely and easily applicable to our daily life. Considering that chili peppers have been a vital part of culinary cultures worldwide and have a long history of use for flavoring, so it is more feasible to be utilized to treat overweight and obesity, compare with medications or other interventions with certain side effects. Dietary chili peppers supplementation or to be food additives, with ideal dosage may be tentative methods for capsaicin to play its protective roles in metabolic health. With the widespread pandemic of overweight and
obesity, the development of more strategies for the treatment of obesity is urgent. Therefore, a better understanding of the role and mechanism of dietary capsaicin consumption and metabolic health can provide critical implications for the early prevention and treatment of obesity.
